33 **Abstract**

34

35 Recent studies have shown that saccadic inward adaptation, i.e. the shortening of saccade amplitude, and
36 saccadic outward adaptation, i.e. the lengthening of saccade amplitude, rely on partially different neu-
37 ronal mechanisms. There is increasing evidence that these differences are based on differences at the tar-
38 get registration or planning stages since outward but not inward adaptation transfers to hand-pointing and
39 perceptual localization of flashed targets. Furthermore, the transfer of reactive saccade adaptation to
40 long-duration overlap and scanning saccades is stronger after saccadic outward adaptation than after sac-
41 cadic inward adaptation, suggesting that modulated target registration stages during outward adaptation
42 are increasingly used in the execution of saccades when the saccade target is visually available for a
43 longer time. The difference in target presentation duration between reactive and scanning saccades is
44 also linked to a difference in perceptual localization of different targets. Flashed targets are mislocalized
45 after inward adaptation of reactive and scanning saccades but targets that are presented for a longer time
46 (stationary targets) are mislocalized stronger after scanning than after reactive saccades. This link be-
47 tween perceptual localization and adaptation specificity suggests that mislocalization of stationary bars
48 should be higher after outward than after inward adaptation of reactive saccades. In the present study we
49 test this prediction. We show that the relative amount of mislocalization of stationary versus flashed bars
50 is higher after outward than after inward adaptation of reactive saccades. Furthermore, during fixation
51 stationary and flashed bars were mislocalized after outward but not after inward adaptation. Thus, our
52 results give further evidence for different adaptation mechanisms between inward and outward adapta-
53 tion and harmonize some recent research.

64

65 Introduction

66

67 Clear vision is based on the ability to make saccades as accurately as possible. The accuracy of the sac-
68 cadic system is maintained by the mechanism of saccadic adaptation. Saccadic inaccuracies may occur as
69 a consequence of eye muscle weakness (Kommerell et al., 1976; Abel et al., 1978; Optican et al., 1985)
70 but may also be artificially generated and studied in the laboratory by a systematic intra-saccadic dis-
71 placement of the saccade target (McLaughlin, 1967; Miller et al., 1981). The resulting difference be-
72 tween the eye landing position and the post-saccadic visual location of the target induces the adjustment
73 of transformation parameters between the visual input and the motor commands. This adjustment reduces
74 the post-saccadic visual error during subsequent trials and allows the eyes to land closer to the shifted
75 target. The effectiveness of saccadic adaptation depends on the location, timing, and consistency of the
76 post-saccadic error (Wallman & Fuchs, 1998; Shafer et al., 2000; Noto & Robinson, 2001; Collins et al.,
77 2009; Havermann & Lappe, 2010; Zimmermann & Lappe, 2010; Panouilleres et al., 2011).

78 Saccadic adaptation is specific to the direction and amplitude of the saccade (Deubel et al., 1986; Deubel,
79 1987; Albano & King, 1989; Frens & Van Opstal, 1994; Collins et al., 2007; Schnier et al., 2010), to the
80 initial eye position (Zimmermann & Lappe, 2011; Havermann et al., 2011), and to the particular saccade
81 type.

82 Saccade types can be distinguished by the way the saccade is triggered. Reactive saccades are elicited by
83 a sudden appearance of a saccade target and simultaneous disappearance of the fixation point (Deubel,
84 1995; Hopp & Fuchs, 2004). Because there is only limited time to integrate spatio-temporal target infor-
85 mation reactive saccades are thought to receive target localization signals from comparatively early visu-
86 al areas in the oculomotor pathway (Pierrot-Deseilligny, 1991; Gaymard et al., 2003; Müri & Nyffeler,
87 2008). During overlap saccades, on the other hand, the fixation point and the saccade target are presented
88 simultaneously for a certain period of time and the saccade is initiated when the fixation point turns off
89 (Deubel, 1995; Hopp & Fuchs, 2004). Because there is more time to integrate spatio-temporal target in-
90 formation overlap saccades might receive target localization signals from higher visual areas in the ocu-
91 lomotor pathway (Deubel, 1999; Rivaud et al., 1994; Müri & Nyffeler, 2008). The same would apply to
92 scanning saccades, which are self-paced and internally triggered saccades within a continuously present
93 scene, and thus do not contain trigger signals for saccade execution (Deubel, 1995; Hopp & Fuchs,
94 2004).

95 Many transfer studies revealed that adaptation transfer differs between these different saccade types and
96 is often not symmetric (reviewed in Pélisson et al. (2010)). There is a strong transfer from scanning to
97 reactive saccades but a comparatively weak, though often significant, transfer in the opposite direction

98 (Erkelens & Hulleman, 1993; Fujita et al., 2002; Gaveau et al., 2005; Collins & Doré-Mazars, 2006; Cot-
99 ti et al., 2007; Zimmermann & Lappe, 2009). Because of the non-zero and asymmetric transfer one may
100 argue for a common locus in the final common saccadic pathway, together with other adaptation loci that
101 are more specific to each saccade category (Alahyane et al., 2007). Besides, differences in the temporal
102 properties of the generation of reactive and scanning saccades may lead to asymmetric transfer. Reactive
103 saccades have shorter latencies than scanning saccades, and are thus presumably driven by neurons with
104 short latencies and limited temporal integration. Thus, adaptation of reactive saccades should lead to only
105 minor adaptation of scanning saccades since scanning saccades presumably involve both short latency
106 and long latency neurons. Scanning saccade adaptation, in contrast, should lead to clear adaptation of
107 reactive saccades since both involve short latency neurons. Indeed, the amount of transfer between reac-
108 tive and overlap saccades depends on the duration of the overlap (Deubel, 1999; Schnier & Lappe, 2011).
109 Saccadic adaptation not only influences saccade amplitudes but also visual localization. This pertains to
110 the perception of visual targets flashed before an adapted saccade (Awater et al., 2005; Bruno & Mor-
111 rone, 2007; Collins et al., 2007; Georg & Lappe, 2009; Schnier et al., 2010), the pointing to a flashed
112 target with the hand (Cotti et al., 2007; Bruno & Morrone, 2007; Hernandez et al., 2008; Cotti et al.,
113 2009; but see Kroller et al., 1996, McLaughlin et al., 1968, Cecala and Freedman, 2008, 2009), and even
114 the apparent position of the saccade target itself (Bahcall & Kowler, 1999). The strength of mislocaliza-
115 tion depends on the saccade type, but also on the properties of the target. Zimmermann & Lappe (2009)
116 investigated changes in visual localization of stationary (i.e. long visible) and flashed (i.e. short visible)
117 bars after adaptive shortening of reactive and scanning saccades. They observed that briefly presented
118 localization probes were mislocalized after adaptation of both saccade types while stationary localization
119 probes were only mislocalized after adaptation of scanning saccades. Since flashed probes resemble a
120 potential target for reactive saccades and stationary probes resemble a potential target for scanning sac-
121 cades the observed asymmetry of visual localization resembles the asymmetry of transfer behavior be-
122 tween reactive and scanning saccades (Deubel, 1999; Collins & Doré-Mazars, 2006; Alahyane et al.,
123 2007; Cotti et al., 2007; Pélisson et al., 2010). The link may lie in the temporal properties of target loca-
124 lization and saccade generation, involving short latency neurons for reactive saccades and flashed probes
125 and short plus long latency neurons for scanning saccades and stationary probes. In this view, one may
126 argue that localization judgements and saccade targeting share a common representation. This is also
127 supported by findings that mislocalization also occurs during periods of fixation (Moidell and Bedell,
128 1988, Zimmermann and Lappe, 2010, Schnier et al., 2010, Garaas and Pomplun, 2011), suggesting that
129 saccadic adaptation affects visual localization at the target registration or planning stages.

130 There is a second factor that divides saccadic adaptation properties, namely the distinctions between in-
131 ward (or amplitude shortening) and outward (or amplitude lengthening) adaptation. Saccade amplitude is

132 lengthened when the saccade target is shifted in the primary saccade direction. Saccade amplitude is
133 shortened when the target is shifted against the primary saccade direction. Many studies revealed differ-
134 ences between inward and outward adaptation (reviewed in Pélisson et al. (2010)). For example, more
135 trials with target displacement are required to reach a steady adaptation state during outward adaptation
136 than during inward adaptation. Furthermore, the corresponding final gain level is lower and less stable
137 after outward adaptation than after inward adaptation (Miller et al., 1981; Semmlow et al., 1989; Straube
138 & Deubel, 1995; Straube et al., 1997; Hernandez et al., 2008; Golla et al., 2008; Ethier et al., 2008; Pa-
139 nouilleres et al., 2009; Zimmermann & Lappe, 2010; Schnier & Lappe, 2011). Finally, differences have
140 been also observed in the adjustment of saccade dynamics (peak velocity, duration) between the inward
141 and outward adaptation procedures (Golla et al. 2008; Ethier et al. 2008; Schnier and Lappe, 2010).

142 Transfer from reactive saccades to overlap and scanning saccades is significantly stronger after outward
143 adaptation than after inward adaptation (Schnier & Lappe, 2011). Such a transfer difference was not
144 found for the gap and the memory-guided saccade type suggesting that the amount by which gain trans-
145 fer differed between inward and outward adaptation for scanning and overlap saccades seems to be es-
146 sentially related to the presentation duration of the saccade target.

147 The above mentioned studies on visual localization after saccadic adaptation also support differences
148 between inward and outward adaptation. Hernandez et al. (2008) found changes in hand pointing direc-
149 tion after outward adaptation, but not after inward adaptation. Zimmermann & Lappe (2010) showed that
150 visual localization of eccentric targets during fixation was much more susceptible to saccadic adaptation
151 for outward than for inward adaptation. These results, together with those of Schnier & Lappe (2011) and
152 Ethier et al. (2008) suggest that there is a stronger modulation of target localization stages after outward
153 than after inward adaptation of reactive saccades. In this view, target localization stages, located before
154 the sensorimotor transformation, are especially used in the execution of overlap and scanning saccades,
155 leading to a higher amount of transfer to these latter saccade types dependent on whether target localiza-
156 tion stages are modulated by saccadic adaptation or not. This in turn implies that target localization for
157 the execution of reactive saccades may be partially different from that of overlap or scanning saccades
158 because there is less time to integrate spatio-temporal target information.

159 Since there is a stronger adaptation transfer from reactive to long-duration overlap or scanning saccades
160 after outward than after inward adaptation of reactive saccades (Schnier and Lappe, 2011), we wondered
161 whether the mislocalization of stationary probes that was observed for inward adaptation of scanning but
162 not reactive saccades (Zimmermann & Lappe, 2009), reflecting the asymmetric transfer behavior be-
163 tween both saccade types, may be observed for reactive saccades when outward rather than inward adap-
164 tation is performed. In this context we also tested the adaptation induced localization judgements of
165 flashed and stationary bars during periods of fixation. If outward adaptation of reactive saccades affects

166 target localization stages that are also used for saccades with a longer target presentation duration, as for
167 example scanning saccades, and adaptation of these latter saccade types affects target localization stages
168 as shown by the adaptation induced mislocalization during periods of fixation (Cotti et al., 2007; Cotti et
169 al., 2009), we wondered whether outward adaptation of reactive saccades induces mislocalization of
170 flashed but also stationary bars during periods of fixation.

171

172

173 **Methods**

174

175 **Experimental settings**

176

177 Stimuli were presented on a 21" monitor (Eizo FlexScan F930) with a vertical frequency of 120 Hz at a
178 resolution of 1024 x 768 pixels. Participants were seated 57 cm in front of the stimulus monitor with
179 their chin supported by a chin rest. This setting results in a visual field of 40 deg x 30 deg. Experiments
180 were done in complete darkness with a background luminance below 0.0006 cd/m². This low luminance
181 was chosen to remove all visible background stimulation and particularly the borders of the monitor
182 screen which otherwise could provide visual references. Additionally, the monitor was covered with a
183 dark foil that reduced the luminance by about two log units to prevent effects of phosphor persistence of
184 the monitor. Nevertheless, all stimuli presented in this experiment were clearly visible under photopic
185 conditions (cf. Georg et al. (2008) for a detailed description).

186

187 **Eye movement recording**

188

189 Eye movements were recorded with an EyeLink 1000 eye tracker (Desktop Mount Base System, SR Re-
190 search, LTD, Canada) using signals from the pupil and the corneal reflex. The recorded data comprised
191 online events and raw gaze position samples (at 1000 Hz) from the tracked left eye. Saccades were de-
192 tected online as soon as eye velocity crossed a velocity threshold of 22 deg/sec and an acceleration thre-
193 shold of 4000 deg/sec². Messages were written into the eyelink file in order to structure and organize this
194 file corresponding to the course of the program. Those messages include all necessary program informa-
195 tion. Each eyelink file from each experimental session was offline checked for drifts that might have oc-
196 curred. No drifts were detected.

197

198 **Participants**

199

200 Thirteen subjects (5 females, 8 males, 1 author, 12 naive, age range: 23-38 years) participated in this
201 study. All of them had normal or corrected to normal vision and were experienced in eye movement ex-
202 periments. Before starting the experiment participants gave informed consent in accordance with the
203 Declaration of Helsinki and the guidelines of the ethics committee of the Department of Psychology,
204 which approved this study.

205

206 **Procedure for reactive saccade adaptation**

207

208 Fixation point (FP) and target (T1) were red disks with a radius of 0.5 deg and a luminance of 0.13
209 cd/m^2 . Both disks were clearly visible under photopic conditions. At the beginning of each trial FP was
210 presented 12 deg to the left of the center of the screen. Correct fixation was checked online. After a vari-
211 able time between 300 and 700 ms FP disappeared and subjects had to perform a saccade towards the
212 simultaneously appearing target T1, which was 8 deg to the right of the center of the screen inducing a
213 20 deg reactive saccade. When eye position exceeded a three deg trigger threshold rightwards from FP
214 (saccade onset), the target T1 stepped 6 deg inwards, or 6 deg outwards to location T2 equivalent to a 30
215 % inward or outward target step. The direction of the step (inward/outward) depended on the particular
216 experimental session and never changed within each session. T2 remained visible for further 500 ms.
217 After a further 550 ms the next trial began.

218

219 **Procedures for test localization trials**

220

221 At the beginning of each localization trial FP was presented 12 deg to the left of the center of the screen.
222 Correct fixation was the trigger to proceed with the trial.

223

224 **Localization judgements of stationary bars**

225

226 A bar (width 0.3 deg, height 2 deg, and luminance 0.13 cd/m^2) was presented at a random position within
227 a rectangular space (width 4 deg, height 2 deg) centered 2 deg directly above the target position T1. After
228 a variable time between 800 and 1200 ms the fixation point was extinguished and, simultaneously, the
229 target T1 appeared. Subjects performed a saccade to T1. At saccade onset the bar was extinguished. The
230 target remained visible for further 500 ms. Thereafter a mouse pointer appeared at a random position 4

231 deg beyond the horizontal centerline of the screen and subjects had to indicate the perceived position of
232 the stationary bar (cf. Figure 1 A for a timeline view). Thus, localization judgements were done on a
233 completely dark stimulus screen without any visual references.

234 In some trials the target disappeared at saccade onset together with the bar. These target-off trials were
235 introduced to remove any post-saccadic visual references that might affect the localization judgement.
236 Accordingly, the trials in which the target remained visible after the saccade were named target-on trials.

237

238 **Localization judgements of flashed bars**

239

240 The FP remained visible for a variable time between 800 and 1200 ms. Then, the fixation point was ex-
241 tinguished, the target T1 appeared, and subjects performed a saccade to T1. 80 ms after T1 appearance
242 and thus on average about 130 ms before saccade onset a bar was presented for 25 ms at a random posi-
243 tion within a rectangular space (width 4 deg, height 2 deg) centered 2 deg directly above the target posi-
244 tion T1. After saccade onset the target disappeared during target-off trials, or remained visible for further
245 500 ms during target-on trials. Thereafter a mouse pointer appeared at a random position 4 deg beyond
246 the horizontal centerline of the screen. Subjects had to indicate the perceived position of the flashed bar
247 (cf. Figure 1 A for a timeline view). Thus, localization judgements were done on a completely dark sti-
248 mulus screen without any visual references.

249 Comparison between localization trials for the judgment of stationary bars and localization trials for the
250 judgment of flashed bars reveals that both differed only in that in the former the localization bar was vis-
251 ible for 800 to 1200 ms together with FP whereas in the latter the bar was flashed for 25 ms after FP was
252 turned off.

253

254 Figure 1 about here

255

256 **Localization judgements during fixation**

257

258 In some trials, participants had to withhold the saccade and perform the visual localization while keeping
259 fixation. A computer voice announced each fixation localization trial, and a modified FP, i.e. a red circle
260 with a radius of 0.5 deg and a thickness of 0.1 deg, reminded subjects to keep fixation during the follow-
261 ing trial and to indicate localization judgements from the corner of their eyes. Either stationary bars (va-
262 riable presentation time between 925 ms - 1325 ms) or flashed bars (25 ms) were presented at a random
263 position within the same rectangular space as in the other localization trials. Thereafter the modified FP
264 vanished and a mouse pointer appeared at a random position 4 deg beyond the horizontal centerline of

265 the screen. Subjects had to indicate the perceived position of the stationary or flashed bar without moving
266 their eyes (cf. Figure 1 B for a timeline view). Thus, localization judgements were done on a completely
267 dark stimulus screen without any visual references.

268

269 **Sessions**

270

271 Each subject participated in four experimental sessions, two with inward adaptation and two with out-
272 ward adaptation. Experimental sessions were performed in random order. Before each experimental ses-
273 sion subjects were informed about the particular task, the total number of trials, and the approximate du-
274 ration of the session. Additionally they were instructed to click in the outermost left corners of the stimu-
275 lus screen whenever they were not able to localize the bar.

276

277 **Course of an experimental session**

278

279 Each session consisted of 180 pre-adaptation trials, 200 adaptation trials, and 180 post-adaptation trials.
280 Pre- and post-adaptation phases contained all test localization trials, 15 each of target-on trials with a
281 stationary bar, target-on trials with a flashed bar, target-off trials with a stationary bar, target-off trials
282 with a flashed bar, fixation trials with a stationary bar, and fixation trials with a flashed bar. The remain-
283 ing 90 trials in the pre- and post-adaptation phases were reactive reinforcing trials without the target step
284 in the pre-phase and with the 6 deg target step (inward/outward) in the post-phase. All trials in the pre-
285 and post-adaptation phases were completely intermixed.

286

287 **Data analysis**

288

289 Mathematica 7.0 was used for all data analysis. For a saccade to enter analysis, its start point had to be
290 within a circle of 2.5 deg diameter around the fixation point, its amplitude had to be between 10 and 30
291 deg, its duration had to be between 20 and 100 ms, and its latency had to be between 80 and 400 ms.
292 With these criteria $93.0 \% \pm 2.0$ (SE) of all trials with a saccade to perform were accepted in the inward
293 adaptation experimental sessions and $92.5 \% \pm 2.4$ (SE) were accepted in the outward adaptation experi-
294 mental sessions. In some trials during the pre- and post-adaptation phase, subjects also had to localize a
295 flashed or stationary bar after the saccade. Mouse clicks outside a circle of 8 deg diameter around the
296 true bar position were excluded from analysis (less than 1%).

297 For fixation localization trials, gaze had to be within a circle of 2.5 deg diameter around the fixation point

298 until the final mouse click. Within this circle only microsaccades with an amplitude less than 1 deg were
299 allowed. $95.9 \% \pm 1.3$ (SE) of all fixation localization trials were accepted in the inward adaptation exper-
300 imental sessions and $96.5 \% \pm 0.9$ (SE) were accepted in the outward adaptation experimental sessions.
301 Mouse clicks outside a circle of 8 deg diameter around the true bar position were excluded from analysis
302 (less than 1%).

303

304

305 **Results**

306

307 **Adaptation**

308

309 Figure 2 shows example sessions for inward (A) and outward (B) adaptation. Clearly there is a reduction
310 of saccade amplitude during saccadic inward adaptation and an increase of saccade amplitude during
311 saccadic outward adaptation for all trial types.

312 Averaged over all subjects the mean amplitude of pure reactive saccades before adaptation phase was
313 $18.78 \text{ deg} \pm 0.20$ (SE) in the inward adaptation sessions and 18.55 ± 0.24 (SE) in the outward adaptation
314 sessions (cf. horizontal gray rectangles in the pre-phase of figures 2 A and B). After inward adaptation
315 the mean amplitude value of pure reactive saccades decreased to $14.36 \text{ deg} \pm 0.36$ (SE) (cf. horizontal
316 gray rectangle in the post-phase of figure 2 A). This decrease corresponded to a mean gain change of
317 $-23.6 \% \pm 1.4$ (SE). After outward adaptation the mean amplitude value of pure reactive saccades in-
318 creased to 21.49 ± 0.28 (SE) (cf. horizontal gray rectangle in the post- phase of figure 2 B). This increase
319 corresponded to a mean gain change of $15.9 \% \pm 0.9$ (SE). The gain change was significantly lower in
320 the outward compared to the inward adaptation sessions (paired t-test with absolute values, $p < 0.0005$).

321 The gain change values for saccade trials with localization (circles and triangles) were similar to the gain
322 change values for the pure reactive saccade trials. Thus, the presentation of the bar did not affect gain
323 change (oneway repeated measures ANOVA comparing gain change during pure reactive saccades, tar-
324 get-on localization trials (separate for stationary and flashed bars), and target-off localization trials (sepa-
325 rate for stationary and flashed bars); inward: $F(4,48)=2.291$, $p=0.073$; outward: $F(4,48)=1.905$, $p=0.125$).

326

327 Figure 2 about here

328

329

330 **Localization after reactive saccades**

331

332 **Absolute mislocalization of stationary and flashed bars**

333

334 To determine the mislocalization of stationary and flashed bars we compared localization judgements
 335 before and after adaptation in each condition. In each trial, the horizontal mouse click location relative to
 336 the horizontal true location of the bar was measured, and the resulting values were averaged to provide
 337 estimates of pre-adaptation and post-adaptation localization judgements. Localization judgements of sta-
 338 tionary bars before adaptation were $-0.16 \text{ deg} \pm 0.17 \text{ (SE)}$ (outward: $-0.39 \text{ deg} \pm 0.18 \text{ (SE)}$) in the target-
 339 on condition and $0.02 \text{ deg} \pm 0.24 \text{ (SE)}$ (outward: $-0.48 \text{ deg} \pm 0.25 \text{ (SE)}$) in the target-off condition. For
 340 flashed bars localizations judgements before adaptation were $-0.06 \text{ deg} \pm 0.23 \text{ (SE)}$ (outward: -0.20 deg
 341 $\pm 0.29 \text{ (SE)}$) in the target-on condition and $-0.26 \text{ deg} \pm 0.28 \text{ (SE)}$ (outward: $-0.61 \text{ deg} \pm 0.30 \text{ (SE)}$) in the
 342 target-off condition. After adaptation localizations judgements of stationary bars were $-1.40 \text{ deg} \pm 0.42$
 343 (SE) (outward: $2.56 \text{ deg} \pm 0.25 \text{ (SE)}$) in the target-on condition and $-0.98 \text{ deg} \pm 0.29 \text{ (SE)}$ (outward: 1.87
 344 $\text{deg} \pm 0.25 \text{ (SE)}$) in the target-off condition, and of flashed bars $-3.23 \text{ deg} \pm 0.28 \text{ (SE)}$ (outward: 3.30 deg
 345 $\pm 0.36 \text{ (SE)}$) in the target-on condition and $-2.32 \text{ deg} \pm 0.24 \text{ (SE)}$ (outward: $2.30 \text{ deg} \pm 0.29 \text{ (SE)}$) in the
 346 target-off condition. Negative values correspond to mislocalization against the original saccade direction,
 347 positive values indicate mislocalization in the original saccade direction.

348 To plot and statistically analyze the data we calculated the differences between pre-adaptation and post-
 349 adaptation localization judgements for each condition. Figure 3 shows the mean adaptation-induced hori-
 350 zontal mislocalization (localization judgements (post) - localization judgements (pre)) of stationary and
 351 flashed bars in the target-on and target-off conditions after inward (A) and outward (B) adaptation. Nega-
 352 tive values in A correspond to mislocalization against the original saccade direction (inward adaptation),
 353 positive values in B indicate mislocalization in the original saccade direction (outward adaptation).

354

355 Figure 3 about here

356

357 After inward adaptation and with a post-saccadic visual reference (target-on) the mean mislocalization of
 358 stationary bars was $-1.24 \text{ deg} \pm 0.35 \text{ (SE)}$ and the mean mislocalization of flashed bars was $-3.17 \text{ deg} \pm$
 359 0.24 (SE) . Both values were significantly different from zero (t-tests, stationary: $p < 0.005$, flashed:
 360 $p < 0.0005$). Without a post-saccadic visual reference (target-off) the mean mislocalization of stationary
 361 bars was $-1.01 \text{ deg} \pm 0.26 \text{ (SE)}$ and the mean mislocalization of flashed bars was $-2.06 \text{ deg} \pm 0.19 \text{ (SE)}$.
 362 Again both values were significantly different from zero (t-tests, stationary: $p < 0.005$, flashed: $p < 0.0005$).
 363 After outward adaptation and with a post-saccadic visual reference (target-on) the mean mislocalization
 364 of stationary bars was $2.95 \text{ deg} \pm 0.18 \text{ (SE)}$ and the mean mislocalization of flashed bars was $3.51 \text{ deg} \pm$

365 0.27 (SE). Without a post-saccadic visual reference (target-off) the mean mislocalization of stationary
366 bars was $2.35 \text{ deg} \pm 0.16 \text{ (SE)}$ and the mean mislocalization of flashed bars was $2.91 \text{ deg} \pm 0.17 \text{ (SE)}$.
367 All values were significantly different from zero (t-tests, $p < 0.0005$).

368 A three-way repeated measures ANOVA with factors adaptation direction (inward/outward), post-
369 saccadic visual target reference (target-on/target-off), and bar type (stationary/flashed) showed a signifi-
370 cant dependence of the mean mislocalization on all three main factors (adaptation direction:
371 $F(1,12)=32.341$, $p < 0.0005$; post-saccadic visual target reference: $F(1,12)=30.348$, $p < 0.0005$); bar type:
372 $F(1,12)=89.514$, $p < 0.0005$). Additionally there was a significant interaction between adaptation direction
373 and bar type ($F(1,12)=6.186$, $p < 0.05$) and between post-saccadic visual target reference and bar type
374 ($F(1,12)=22.003$, $p < 0.005$). The interaction of all three main factors was also significant ($F(1,12)=22.182$,
375 $p < 0.005$).

376 Post-hoc paired t-tests then revealed that after inward adaptation the mean mislocalization of flashed bars
377 was significantly larger than the mean mislocalization of stationary bars (target-on, target-off, $p < 0.0005$).
378 Comparison of the mean mislocalization in the target-on and target-off conditions revealed a contribution
379 of the post-saccadic visual reference on final localization judgements. It was especially pronounced for
380 the flashed bar condition, in which mean mislocalization in the target-on condition was significantly
381 larger than mean mislocalization in the target-off condition ($p < 0.0005$). For stationary bars the difference
382 was not significant ($p = 0.11$), which might have to do with the smaller overall mislocalization. However,
383 because in both cases mislocalization occurred also in the target-off conditions, post-saccadic target in-
384 formation cannot be the only source for the mislocalization, i.e. the present target as a visual landmark
385 can be only responsible for parts of the total mislocalization (cf. McConkie & Currie (1996); Deubel et
386 al. (1996); Awater & Lappe (2006)).

387 Furthermore, post-hoc paired t-tests clarified that after saccadic outward adaptation, although not as pro-
388 nounced as after saccadic inward adaptation, mean mislocalizations of flashed bars (target-on/target-off)
389 were significantly larger than mean mislocalizations of stationary bars (target-on/target-off) (target-on,
390 target-off, $p < 0.005$). Consistent with a contribution of the post-saccadic visual reference on final locali-
391 zation judgements, mean mislocalizations in the target-on conditions (flashed/stationary) were
392 significantly larger than mean mislocalizations in the target-off conditions (flashed/stationary) (flashed:
393 $p < 0.005$, stationary: $p < 0.0005$).

394 Finally, the absolute values of mean mislocalizations of stationary bars (target-on/target-off) were
395 significantly larger after saccadic outward adaptation than after saccadic inward adaptation (paired t-
396 tests, target-on: $p < 0.0005$, target-off: $p < 0.0005$; note that in these tests values for inward adaptation were
397 multiplied by (-1) in order to make the two adaptation directions comparable). The difference was less
398 pronounced in the mean mislocalizations of flashed bars in the target-off condition and not significant in

399 the mean mislocalizations of flashed bars in the target-on condition (paired t-tests, target-on: $p=0.08$, tar-
 400 get-off: $p<0.005$ (but close to 0.005)). The larger difference in mean mislocalization of flashed bars be-
 401 tween the target-on and target-off conditions after saccadic inward adaptation in comparison to after sac-
 402 cadic outward adaptation suggest a higher contribution of post-saccadic visual references to localization
 403 judgements after saccadic inward adaptation. The references provided by the saccade target induce mis-
 404 localization because the target stepped during the saccade. Thus, the reference information provided by
 405 the target is incorrect. Reliance on this information, therefore, contributes to mislocalization.

406

407 **Comparison of mislocalization of stationary to flashed bars**

408

409 We were interested in how much stationary bars were mislocalized in relation to flashed bars after in-
 410 ward and outward adaptation of reactive saccades. Therefore, we calculated the relative mislocalization
 411 (mislocalization of stationary bars divided by mislocalization of flashed bars) to normalize for the differ-
 412 ence in mislocalization strength of flashed bars between the two adaptation directions.

413

414 Figure 4 about here

415

416 Figure 4 A shows the percentage ratio of mislocalization of stationary bars in relation to flashed bars af-
 417 ter saccadic inward adaptation. The corresponding values are $37.9 \% \pm 9.3$ (SE) in the target-on condi-
 418 tion and $49.8 \% \pm 12.1$ (SE) in the target-off condition. Figure 4 B shows the ratio of mislocalization of
 419 stationary bars in relation to flashed bars after saccadic outward adaptation. The corresponding values are
 420 $86.3 \% \pm 4.6$ (SE) in the target-on condition and $82.6 \% \pm 5.8$ (SE) in the target-off condition. A two-
 421 way repeated measures ANOVA with factors adaptation direction (inward/outward) and post-saccadic
 422 visual target reference (target-on/target-off) showed a significant dependence of the percent amount of
 423 mislocalization on the adaptation direction ($F(1,12)=8.80$, $p<0.05$). The interaction was not significant
 424 ($F(1,12)=3.74$, $p=0.08$). Paired t-tests between the values after saccadic inward and outward adaptation
 425 confirmed that the ratio of mislocalization (mean mislocalization of stationary bars/mean mislocalization
 426 of flashed bars $\cdot 100$) is significantly higher after outward adaptation than after inward adaptation (tar-
 427 get-on: $p<0.005$, target-off: $p<0.05$).

428

429

430

431 **Localization judgements during fixation**

432

433 Localizations judgements during fixation and before adaptation were $-0.51 \text{ deg} \pm 0.44 \text{ (SE)}$ (outward:
434 $-0.86 \text{ deg} \pm 0.48 \text{ (SE)}$) for stationary bars and $-1.16 \text{ deg} \pm 0.44 \text{ (SE)}$ (outward: $-1.54 \text{ deg} \pm 0.46 \text{ (SE)}$) for
435 flashed bars. After adaptation localization judgements of stationary bars were $-0.71 \text{ deg} \pm 0.38 \text{ (SE)}$
436 (outward: $0.57 \text{ deg} \pm 0.52 \text{ (SE)}$) and of flashed bars $-1.37 \text{ deg} \pm 0.32 \text{ (SE)}$ (outward: $0.03 \text{ deg} \pm 0.46$
437 (SE)).

438 Figure 5 shows the mean adaptation-induced mislocalizations (localization judgements (post) - localiza-
439 tion judgements (pre)) of stationary and flashed bars during fixation.

440

441 Figure 5 about here

442

443 There was no significant mislocalization after inward adaptation (t-tests, stationary: $p=0.20$, flashed:
444 $p=0.20$). After outward adaptation, however, both flashed and stationary bars were significantly misloca-
445 lized with quite similar magnitude (stationary: $1.43 \text{ deg} \pm 0.22 \text{ (SE)}$, flashed: $1.57 \text{ deg} \pm 0.21 \text{ (SE)}$, t-
446 tests, $p<0.0005$). A two-way repeated measures ANOVA with factors adaptation direction (in-
447 ward/outward) and bar type (stationary/flashed) corroborate the similar magnitude of mislocalizations of
448 both bar types ($F(1,12)=0.24$, $p=0.63$, interaction: $F(1,12)=0.30$, $p=0.59$) and the significantly larger mis-
449 localizations after outward than after inward adaptation of reactive saccades ($F(1,12)=23.23$, $p<0.0005$).

450

451

452 **Discussion**

453

454 Our results showed that the ratio of mislocalization of stationary bars in relation to flashed bars was
455 higher after saccadic outward adaptation than after saccadic inward adaptation of reactive saccades. Dur-
456 ing periods of fixation neither bar type was mislocalized after saccadic inward adaptation but both were
457 mislocalized after outward adaptation.

458 Our study was conducted to corroborate the differences between saccadic inward and outward adapta-
459 tion, observed in the study of Schnier & Lappe (2011), by establishing the link between these results and
460 those of Zimmermann & Lappe (2009). Zimmermann & Lappe (2009) investigated changes in visual
461 localization for two different probe durations, i.e. a long duration (stationary) probe and a short duration
462 (flashed) probe, after inward adaptation of reactive and scanning saccades. They found that flashed but
463 not stationary probes were mislocalized after inward adaptation of reactive saccades. However, both
464 probes were mislocalized after inward adaptation of scanning saccades. Since there is strong transfer of
465 inward adaptation from scanning to reactive saccades, but only weak transfer in the opposite direction
466 (Deubel, 1999; Collins & Doré-Mazars, 2006; Alahyane et al., 2007; Cotti et al., 2007; Pélisson et al.,

467 2010), and since stationary localization probes resemble typical targets for scanning while flashed probes
468 resemble targets for reactive saccades, the asymmetry of mislocalization suggests that the selectivity of
469 visual mislocalization after inward adaptation of a particular saccade type fits the adaptation selectivity
470 in the motor behavior (Zimmermann & Lappe, 2009).

471 Schnier & Lappe (2011) studied adaptation transfer after outward adaptation. Transfer from reactive to
472 scanning and overlap saccades was stronger after outward than after inward adaptation. In the light of the
473 above considerations, this predicted that stationary localization probes should be more mislocalized after
474 outward than after inward adaptation of reactive saccades. Indeed, when we compared the relative
475 amount of mislocalization of stationary versus flashed bars after saccadic inward adaptation with the cor-
476 responding values after saccadic outward adaptation (cf. Figure 4) this is exactly what we found. Also as
477 expected, the absolute mislocalization of stationary bars was higher after outward adaptation than after
478 inward adaptation (cf. Figure 3). Since this was also true for flashed bars, effects of saccadic outward
479 adaptation on visual localization and effects of saccadic inward adaptation on visual localization must
480 rely on different processes. One might speculate that an essential difference lies in the substantial visual
481 error that persists after saccadic outward adaptation but not after saccadic inward adaptation, since out-
482 ward adaptation remains incomplete for much longer than inward adaptation (Zimmermann & Lappe,
483 2010). Indeed, when inducing adaptation with a long-lasting post-saccadic visual error (Robinson et al.,
484 2003) Zimmermann & Lappe (2010) revealed mislocalization during fixation also after the inward adap-
485 tation procedure. In addition, the availability of post-saccadic target information also provided a contri-
486 bution to the mislocalization, as seen by a larger amount of mislocalization in the target-on conditions in
487 comparison to the target-off conditions for both inward and outward adaptation. Thus, the post-saccadic
488 target is used as a visual landmark, but is responsible only for parts of the mislocalization (McConkie &
489 Currie, 1996; Deubel et al., 2002; Awater & Lappe, 2006).

490 Now one might ask at which neural stage outward adaptation of reactive saccades differs from inward
491 adaptation of reactive saccades, and how this difference leads to the observed differences in mislocaliza-
492 tion of stationary versus flashed localization probes. It is unlikely that the difference lies close to the mo-
493 tor stage, i.e. late in oculomotor processing because then it should not affect perception differently. Ra-
494 ther outward adaptation of reactive saccades appears to differ from inward adaptation at the target regis-
495 tration or saccade planning stages (Cotti et al., 2007; Ethier et al., 2008; Hernandez et al., 2008; Cotti et
496 al., 2009; Panouilleres et al., 2009; Zimmermann & Lappe, 2010). Consequently, this means that the
497 differences in localization judgements of stationary probes in relation to flashed probes between inward
498 and outward adaptation should be based on early target localization or planning stages, which are used in
499 the localization judgements of stationary bars, that are more strongly modulated after outward adaptation
500 than after inward adaptation of reactive saccades. This suggestion is consistent with the observations of a

501 higher amount of transfer from reactive saccades to long duration overlap and scanning saccades after
502 outward adaptation than after inward adaptation (Schnier & Lappe, 2011) if the use of target registration
503 or planning stages depends on the presentation duration of the localization probe or the saccade target
504 (Schnier & Lappe, 2011). This in turn would be consistent with the results of Cotti et al. (2007, 2009)
505 which suggest that target registration or planning stages are modulated after saccadic inward adaptation
506 of voluntarily triggered scanning saccades.

507 Figure 5 shows that even during fixation flashed and stationary bars were mislocalized after the partici-
508 pant underwent saccadic outward adaptation. This finding replicates the results that Zimmermann &
509 Lappe (2010) obtained with flashed stimuli and extends them to stimuli that are continuously visible. The
510 mislocalization during fixation may be explained if localization judgements during fixation use target
511 registration or planning stages which are modulated after saccadic outward but not after saccadic inward
512 adaptation. The similarity of stationary and flashed data might suggest that the use of target registration
513 stages in localization judgements during fixation is independent of the localization probe duration.

514 On a neuronal level, target localization may involve neurons with long integration times that might re-
515 spond to stationary as well as flashed bars. Thus, whenever those neurons are affected by adaptation of a
516 particular saccade type or in a particular direction mislocalization of both probe types should occur. We
517 suggest that this is the case for outward adaptation of reactive saccades, but would assume a similar loca-
518 lization behavior for scanning saccades, independent of the direction of target displacement.

519 The localization targets in our study were located close to the adapted saccade target. Several previous
520 studies have shown that adaptation-induced mislocalization depends on the location of the probe. Awater
521 et al. (2005), Collins et al. (2007) and Schnier et al. (2010) have presented detailed investigations of the
522 spatial range of mislocalization. Since these studies were mostly concerned with localization after
523 adapted saccades, it would be also interesting to investigate in detail the spatial specificity of the mislo-
524 calization effect during fixation described in the present study.

525 In summary, our results show that outward adaptation of reactive saccades and of scanning saccades
526 have an important influence on localization judgements in common, namely the high amount of misloca-
527 lization of stationary bars (cf. Zimmermann & Lappe (2009)). This common mislocalization is likely to
528 stem from early target registration stages that are modulated after outward adaptation of reactive sac-
529 cades as well as after adaptation of scanning saccades. Consistent with this hypothesis we revealed mis-
530 localization of stationary and flashed bars even during fixation. Accordingly, we suggest that stationary
531 and flashed bars should be also mislocalized after adaptation of scanning saccades and during fixation to
532 support the common modulated target registration or planning stage of the outward adaptation procedure
533 of reactive saccades and the adaptation procedure of scanning saccades. Two aspects directly lead to this
534 assumption. First, the adaptation transfer from reactive to overlap or scanning saccades is higher after

535 outward than after inward adaptation of reactive saccades suggesting a common adaptation locus be-
536 tween outward adaptation of reactive saccades and scanning saccades, probably before the sensory-motor
537 transformations (Schnier and Lappe, 2011). Second, adaptation of voluntary (scanning) saccades trans-
538 fers to hand pointing movements (Cotti et al., 2007) or to anti-saccades in the non-adapted direction
539 (Cotti et al., 2009) suggesting a deep involvement of target registration or planning stages in the scanning
540 adaptation procedure.

793

794 **Figure legends**

795

796

797 **Figure 1:**

798

799 Timelines of the trials for the localization judgements of stationary and flashed bars during saccades (A)
 800 and during fixation (B). The solid black lines in A for targets T1 and T2 indicate target-on trials in the
 801 post-adaptation phase. The corresponding dashed lines indicate the timings in the pre-adaptation phase.
 802 The solid gray lines for T1 and T2 indicate target-off trials. T1 was 20 deg rightwards from FP. T2 ap-
 803 peared 6 deg leftwards or rightwards from T1, dependent on the experimental session (inward/outward).
 804 During fixation trials (B) a modified version of the fixation point FP (circle) and an additional computer
 805 voice reminded subjects not to perform a saccade but fixate at the circle. In all conditions the bar (width
 806 0.3 deg, height 2 deg, luminance 0.13 cd/m²) was presented at a random position within an area 4 deg
 807 wide 2 deg high centered 2 deg directly above the target position T1. Subjects had to indicate the per-
 808 ceived bar position with a mouse pointer.

809

810 **Figure 2:**

811

812 Example sessions for the time course of saccadic inward (A) and outward (B) adaptation. The crosses
 813 indicate amplitude values in the pre-adaptation, adaptation, and post-adaptation phases for trials without
 814 bar localization (pure reactive saccades). The horizontal gray rectangles give their means before and after
 815 adaptation. Their thickness indicates twice the standard error. Filled circles indicate amplitude values in
 816 target-on localization trials with a stationary bar. Open circles indicate amplitude values in target-off lo-
 817 calization trials with a stationary bar. Filled triangles indicate amplitude values in target-on localization
 818 trials with a flashed bar. Open triangles indicate amplitude values in target-off localization trials with a
 819 flashed bar.

820

821 **Figure 3:**

822

823 Adaptation-induced mislocalization of stationary (hatched bars) and flashed stimuli (solid bars) after in-
 824 ward (A) and outward (B) adaptation of reactive saccades. Dark gray bars indicate mean adaptation-
 825 induced mislocalizations in the target-on conditions. Light gray bars indicate mean mislocalizations in
 826 the target-off conditions. Error bars are standard errors.

827

828 **Figure 4:**

829

830 Percent ratio of adaptation-induced mislocalization of stationary bars in relation to flashed bars after in-
831 ward (A) and outward (B) adaptation of reactive saccades (Dark gray: target-on, light gray: target-off).
832 Percent ratio between the target-on conditions (inward: 37.9 %, outward: 86.3 %) as well as between the
833 target-off conditions (inward: 49.8 %, outward: 82.6 %) were significantly different from each other
834 (paired t-tests, $p < 0.005$ (target-on), $p < 0.05$ (target-off)). Error bars are standard errors.

835

836 Figure 5:

837

838 Mean mislocalization of stationary (hatched) and flashed (solid) bars after inward (A) and outward (B)
839 adaptation of reactive saccades during fixation. No significant mean mislocalizations were observed for
840 stationary and flashed bars after saccadic inward adaptation (NS, $p > 0.05$ in both t-tests). Both bar types
841 were significantly mislocalized after saccadic outward adaptation (***, $p < 0.0005$ in both t-tests). Error
842 bars are standard errors.
